CONSPECTUS: Our global society generates an unwieldy amount of $CO₂$ per unit time. Therefore, the capture of this greenhouse gas must involve a diverse set of strategies. One solution to this problem is the conversion of $CO₂$ into a more useful chemical species. Again, a multiplicity of syntheses and products will be necessary. No matter how elegant the chemistry is, commercial markets often have little use for a small set of compounds made in tremendous yield. Following this reasoning, the Bocarsly Research Group seeks to develop new electrochemical and photochemical processes that may be of utility in the conversion of CO2 to organic compounds. We focus on investigating proton-coupled charge transfer mechanisms that produce both C1 and carbon−carbon bonded products (C2+).

In early work, we considered the reduction of $CO₂$ to formate at electrocatalytic indium and tin electrodes. These studies demonstrated the key role of surface oxides in catalyzing the reduction of CO₂. This work generated efficient systems for the formation of formate and paved the way to studies using non-copper, intermetallic electrocatalysts for the generation of

 $C2+$ species. Most notable is the efficient formation of oxalate at an oxidized Cr_3Ga electrode. Oxalate has recently been suggested as a potential nonfossil, alternate organic feedstock.

Separately, we have focused on the electrocatalytic effects of pyridine on the reduction of $CO₂$ in aqueous electrolyte. These studies demonstrated that electrodes that normally yield a low hydrogen overpotential (Pd and Pt) show suppressed H_2 evolution and strongly enhanced activity for CO_2 reduction in the presence of pyridinium. Methanol was observed to form in high Faradaic yield at low overpotential using this system. The 6-electron, 6-proton reduction of CO₂ in the presence of pyridinium was intriguing, and significant effort was placed on understanding the mechanism of this reaction both on metal electrodes and on semiconducting photocathodes. P−GaP electrodes were found to provide exceptional behavior for the formation of methanol using only light as the energy source.

The pyridinium studies highlighted the role of protons in the overall reduction of $CO₂$, stimulating our interest in the chemistry of $MnBr(bpy)(CO)_3$ and related compounds. This complex was reported to electrochemically reduce CO_2 to CO. We saw these reports as an opportunity to study the detailed nature of the proton-coupled electron transfer (PCET) mechanism associated with $CO₂$ reduction. Our investigation of this system revealed the role of hydrogen-bonding in $CO₂$ reduction and pointed the way for the construction of a photochemical process for CO generation using a $[(\bar{b}py)(CO)_3\bar{M}n(CN)Mn(bpy)(CO)_3]^{+}$ photocatalyst.

Based on our studies to date, it appears likely that heterogeneous systems can be assembled to convert CO_2 into products that are "beyond C2 products." This may open up new practical chemistry in the area of fossil-based replacements for both synthesis and fuels. Systems with pragmatic efficiencies are close to reality. Electrochemical reactors using heterogeneous electrocatalysts show the stability and product selectivity needed to generate industrial opportunities. Continued growth of mechanistic understanding is expected to facilitate the chemical design of cogent systems for the taming of $CO₂$.

Soc. 2008, 130, 63[4](#page-8-0)2–6344.⁴ This work demonstrates the synthesis of methanol from $CO₂$ at an illuminated p-GaP cathode in the presence of aqueous pyridine/pyridinium. High Faradaic yield was observed at an underpotential, demonstrating that optical energy was efficiently powering the reaction.

1. INTRODUCTION

According to the New York Times (July 7, 2021) based on data collected by The Scripps Institute and the National Oceanic and Atmospheric Administration (NOAA) separately, "Since [May 2014], emissions [of $CO₂$] have continued to soar. The latest full-year average, for 2019, was 409.8 parts per million, about 46 percent higher than the preindustrial average of 280. These findings continue to cast grave concerns by the geophysical community on the impacts of climate change."^{[5](#page-8-0)}

Out of these concerns, two research themes have developed, which are coalesced under the mantle of "Carbon Capture, Utilization, and Storage" (CCUS). Utilization specifically refers to the chemical conversion of carbon dioxide to value-added organic products. One of the research themes specifically focuses on the climate change crisis and the need to remove massive amounts of $CO₂$ from the atmosphere. Under this imperative, it is best to form a product that will remain "locked up" for a geologic time period. The second theme sees carbon dioxide as a valuable chemical feedstock that might replace fossil-based resources, both as a source of organic precursors and as a fuel. In this case, $CO₂$ need not be sequestered, but a chemistry of oxidized carbon (i.e., $CO₂$) must be developed that rivals today's chemistry of reduced carbon (i.e., fossil resources). Taken together, these two themes generate a synthetic carbon cycle that can supplement the natural carbon cycle that is overburdened by our current use of fossil fuels. Both branches of this cycle are endergonic, and thus, the cycle only works if it can be powered efficiently and by a non-fossilfuel source of energy. To help meet this need, the Bocarsly Research Group is interested in the development of electrochemical approaches that efficiently and selectively generate desirable products from $CO₂$, using processes that can be driven by alternate energy resources. We are achieving this result by developing an understanding of the electrocatalytic reduction of $CO₂$ using both metal and semiconductor electrodes. In the case of metal electrodes, we focus on the mechanism and catalytic efficiency of CO₂ reduction at interfaces that can selectively carry out the desired multiple proton-coupled electron transfers (PCETs) under conditions where proton reduction to form H_2 competes with CO_2 reduction. Various formal reduction potentials for $CO₂$ reduction are found in Table 1. It should be noted that the

Table 1. Standard Redox Potentials for the Carbon Dioxide Half Reactions

reaction	E_R° , V vs SHE @ pH = 0
$CO2(g) + e^- \rightarrow CO2$ ^o (aq)	-1.90
$2CO2(g) + 2e^- \rightarrow (CO2)22(aq)$	-0.64
$2CO2(g) + H+(aq) + 2e^- \rightarrow H(CO2)2(aq)$	-0.52
$2CO2(g) + 2H+(aq) + 2e^- \rightarrow H2(CO2)2(aq)$	-0.48
$CO2(g) + H+(aq) + 2e^- \rightarrow HCOO-(aq)$	-0.19
$CO_2(g) + 2H^+(aq) + 2e^- \rightarrow CO(g) + H_2O(aq)$	-0.10
$CO2(g) + 4H+(aq) + 4e- \rightarrow H2CO(aq) + H2O$	-0.07
$2H^{+}(aq) + 2e^{-} \rightarrow H_{2}(g)$	0.00
$CO2(g) + 6H+(aq) + 6e- \rightarrow CH3OH(aq) + H2O$	0.04
$CO_2(g) + 8H^+(aq) + 8e^- \rightarrow CH_4(g) + 2H_2O$	0.17

similarity in the redox potential for the various products suggests that one cannot select between products formed by exerting potential control. The one exception to this statement being the one-electron reduction of CO_2 to CO_2^- . It should also be noted that introducing protons into the chemical reaction (PCET) dramatically lowers the energy of the reaction as measured by the redox potential. In passing, we note that this energy difference suggests that when protons are available, the carbon dioxide radical anion will not be involved in the reaction pathway. On the other hand, the redox potential for proton reduction to H_2 (0.00 V vs SHE) is similar to the PCET reduction potentials for $CO₂$. This indicates that proton-coupled reduction of $CO₂$ will always need to kinetically compete with the reduction of protons to water.

In all cases, the processes of interest are thermodynamically uphill and therefore must be driven by an alternate electricity resource such as wind or solar-derived electricity. This can be accomplished by coupling an alternate energy resource to a standard electrochemical cell. Alternately, one can utilize a cathode composed of a p-type semiconductor to generate photoelectrochemical cells where the reduction of $CO₂$ is driven by the direct absorption of light by the photocathode. In these latter systems, the synthesis of an active and stable interface presents the project goal.

Both approaches hinge on the ability to design and optimize the electrocatalytic nature of the electrode−electrolyte interface. To this end, one needs to consider both heterogeneous PCET occurring at a catalytically active electrode surface and homogeneous electrocatalysis in which a solution species mediates the flow of electrons and protons between the electrode and the $CO₂$ catholyte. While the practicalities of system long-term stability and high current densities favor the implementation of a heterogeneous electrocatalytic interface,

mechanistic understanding of electrocatalytic processes is much more accessible using molecular systems. Additionally, molecular systems provide the opportunity to develop purely photochemical approaches to $CO₂$ reduction. Therefore, we are also interested in dissolved transition metal complexes that photochemically transform $CO₂$ to CO.

It is well appreciated that one of the challenges in converting $CO₂$ into organic products is the exceptionally high reaction barrier associated with the first electron transfer. In significant part, that barrier is associated with the fact that the linear $CO₂$ molecule must rehybridize to generate the anion. That is, the sp hybrid associated with bonding in carbon dioxide must be decreased in s-character to form the anion. As shown in Figure 1, the direct result of this rehybridization is a decrease in the

Figure 1. Bending $CO₂$. One electron reduction of $CO₂$ rehybridizes the frontier orbitals producing the anionic bent structure shown in the upper right of this figure. A lower degree of rehybridization is required forming an $sp³$ hybrid, if the electron transfer is accompanied by a proton transfer.

 CO_2 bond angle as $[CO_2]$ ^{•-} is formed. Thus, the kinetic activation of \tilde{CO}_2 can be thought of as the process of bending.

Facilitating this geometric change is a matter of developing a reaction environment that enhances the rehybridization using a barrier lowering electrocatalyst. DFT calculations indicate that the reaction in Figure 1 requires ∼108 kJ/mol and generates a bond angle of 134° indicating a hybrid state that is approximately $sp^{3/2}$. Adding a proton to this system (PCET) to generate OCOH (bottom of Figure 1) decreases the O−C− O bond angle to 110° , generating approximately sp³ hybridization. This lowers the energy needed to carry out the electron transfer. Similar kinetic improvement can be obtained by coordinating the $CO₂$ reactant to a metal surface or transition metal ion, thereby encouraging the necessary rehybridization. This simple analysis, of course, ignores the other major reaction challenge in the carbon dioxide system: how can carbon−carbon bonds be formed with a minimal expenditure of energy? This challenge is equal to the bond

angle challenge and is a current area of interest in the Bocarsly Research Group.

2. HETEROGENEOUS CARBON DIOXIDE REDUCTION

Within the realm of heterogeneous electrocatalysis, our group has explored copper-free metallic surfaces that are catalytically reactive, generating C1 products such as formate and methanol from $CO₂$, as well as more intriguing (and complex) metalbased interfaces that can promote the formation of C2+ products. These C2+ products include oxalate, acetic acid, ethanol, propanol, and acetone. Attention has been placed on heavy post-transition metals (In, Sn, Bi, Pb) as catalysts for $CO₂$ to formate (i.e., pure C1 chemistry), as these metals have been previously identified to do selective 2-electron reductions.[6](#page-8-0) Our investigation started with In, where we hypothesized that the reaction of interest occurred at a clean metal surface. However, it was revealed that the presence of a surface hydroxide, in the form of $In(OH)_{3}$, was critical to CO_{2} reduction to formate.⁷ Similarly, the surface species on a tin electrode, $Sn(II)(OH)₂$, was found to be responsible for the observed $CO₂$ reduction chemistry.^{[8](#page-8-0)} In both cases, the generation of formate was made possible by the insertion of $CO₂$ into the surface species to form a surface bicarbonate intermediate. Further examination of the post-transition metals observed mechanisms for the Pb and Bi electrodes that differed from the In and Sn electrodes. While In and Sn can be considered oxide-active materials, Pb can be regarded as an oxide-buffered material, where the oxide does not participate directly in $CO₂$ reduction to form a surface bicarbonate. Instead, these oxide-buffered materials provide a buffering effect at the electrode/electrolyte interface that supplies protons required for the electroreduction. Bismuth differs from the previous two materials as it is oxide-independent, meaning the oxide species does not impact the desired electrochemistry.^{[14](#page-9-0)}

Copper and other metals such as Ru and Mo were reported in the late 1970s and early 1980s to reduce $CO₂$ to Cl species.^{[6,](#page-8-0)[15](#page-9-0),[16](#page-9-0)} However, only Cu could accomplish higher-order electrochemical reduction of $CO₂$ to multicarbon species. This remained true until recently, when the Lewis group at California Institute of Technology showed that various Ni_xGa_y intermetallics were capable of $CO₂$ reduction to ethane and ethylene, reaching Faradaic efficiencies (ξ) of approximately 1.5% and 0.5%, respectively. Faradaic efficiencies are calculated using eq 1.

$$
\xi = \frac{Q_{\text{product}}}{Q_{\text{total}}} \tag{1}
$$

Figure 2. SEM images of Ni3Ga thin films synthesized on (A) HOPG and (B) glassy carbon at low (left) and high (right) magnification. While HOPG-plated films are comprised of layered microparticles, glassy carbon variants consist of relatively uniform platelets distributed across the surface. Reproduced with permission from ref [10](#page-9-0). Copyright 2018 IOPscience.

This report was significant because the onset potential for the observed products was found to be −0.48 V vs RHE, which was among the lowest observed for C2 products. This result inspired us to explore intermetallic systems involving a firstrow transition metal coupled with a group 13 metal. Various reduction potentials and Faradaic efficiencies for $CO₂$ reduction using bimetallic systems are displayed in [Table 2](#page-2-0). We chose the very general M_3N stoichiometry and found that $Ni₃Ga$, $Ni₃Al$, and $(Cr₂O₃)(Ga₂O₃)$ systems were electrocatalytic for C2+ products. The products detected varied for the different mixed metal systems, with C2+ ξ values in the range of 0.1% to 2%. However, a highlight of the Cr/Ga system is the ability to generate oxalate in yields as high as 60% .¹³ The observation of high Faradaic efficiency for oxalate formation in aqueous electrolyte is notable for two reasons. First, although oxalate has been previously electrosynthesized, it has required the use of a nonaqueous electrolyte and large overpotentials.¹⁷ Using the Cr/Ga system, good Faradaic efficiency was achieved in aqueous electrolyte at −1.48 V vs Ag/AgCl. This represents a ∼700 mV overpotential, which is much less than previously observed. Second, oxalate is the only two electron system that generates a carbon–carbon bond from $CO₂$ and as such provides a gateway to C2+ organics. Recently, Gruter et al. pointed out that oxalate offers a broad spectrum of opportunities as a feedstock for a variety of organics.¹⁸ Of primary interest is the conversion of oxalate to glycolic species, which have utility in a variety of pragmatic synthetic applications. Gruter has suggested that oxalate may be a considered a "drop in" alternative feedstock for a wide variety of petroleum-based products.^{[18](#page-9-0)}

In our investigation of the Cr/Ga systems, the presence of both oxides proved to be crucial in producing multicarbon products, and it is possible that the presence of surface metal oxide species may be necessary for the observed chemistry for the other intermetallic systems. In the study of $Ni₃Ga$ thin

films, we demonstrated that the products formed were exquisitely sensitive to the electrode material. Thus, for example, switching from a highly ordered pyrolytic graphite (HOPG) electrode to a glassy carbon electrode shut down C2 formation, even though both electrodes are nominally composed of a graphite phase. This result is ascribed to a catalyst deposition effect influenced by the solid support, in which the use of different supports led to altered surface morphologies and electrochemical behaviors.¹⁰

Specifically, $Ni₃Ga$ on HOPG has a distinct rough surface in comparison to $Ni₃Ga$ on glassy carbon, which has a flat and more uniform structure, shown in Figure 2. It is hypothesized that C−C coupling is possible because the high surface area of the Ni₃Ga promoted by the HOPG allows surface-bound intermediates to be in close proximity. Given this finding, it is not quite as surprising that different product yields are observed using a Ni₃Al catalyst distributed on glassy carbon versus a CIGS (copper, indium, gallium, selenium) based p-type photoelectrode.^{[10](#page-9-0),[12,13](#page-9-0)}

In contrast to the above approach, we have also explored the chemistry involved in the homogeneous electroreduction of $CO₂$. Presently, our main vehicle for doing this is complexes based on a MnXbpy (CO) ₃ motif, which is highly selective for the conversion of $CO₂$ to CO. However, we have also explored the reduction of $CO₂$ to C1 and C2+ products using protonated aromatic amines such as pyridinium and imidazole.^{[19](#page-9-0)} While acting in solution, these compounds appear to have a significant inner sphere role under catalytic conditions that brings in some aspects of heterogeneous catalysis. These compounds are excellent for the conversion of $CO₂$ to formate and methanol; however, we have also found that carbon−carbon coupling is possible with appropriate substitution of the aromatic amine catalyst.

3. HOMOGENOUS CARBON DIOXIDE REDUCTION USING PYRIDINE AND AROMATIC AMINES

We first observed the ability of pyridinium to electrocatalyze the reduction of $CO₂$ in 1994 through happenstance and hypothesis testing. Initial tests were conducted using a hydrogenated Pd electrode (β-PdH phase) with 10 mM added pyridine in aqueous electrolyte. The solution was adjusted to pH 5.4, an approximate 1:1 mixture of pyridine and pyridinium ($pK_a = 5.25$), which conveniently buffered the system and interestingly generated hydrogen bonded pyridine−pyridinium pairs[.20](#page-9-0) The aqueous Raman spectrum of [py−H−py]+ is shown in Figure 3.

Figure 3. Raman spectra of pyridinium in water (blue) and an equilibrium mixture of [py-H−py]⁺ and [pyH]⁺ in water (red). Subtraction of the pure pyridinium spectrum from the mixture spectrum yields the aqueous [py−H−py]+ spectrum (green). Adapted with permission from ref [20](#page-9-0). Copyright 2014 Taiwan Association for Aerosol Research.

Cyclic voltammetric studies under either Ar or $CO₂$ suggested an electrocatalytic mechanism that involved a PCET cycle. Bulk electrolysis experiments with aqueous solutions containing both $CO₂$ and pyridine revealed the formation of formaldehyde and methanol. These products were authenticated using ¹H NMR, colorimetric indicators, mass spectroscopic and gas chromatographic data. Further 13 C experiments validated that these products were produced from $CO₂$ and not by degradation of the pyridine catalyst or any other carbon source. While many $CO₂$ reduction systems function at high overpotentials, one of the draws of these initial experiments was the low overpotential (200 mV) needed to reduce $CO₂$ to methanol at a Pd electrode.^{[3](#page-8-0)}

The pyridinium-assisted reduction of $CO₂$ on both Pd and Pt electrodes was exported to a light-driven p-GaP electrode system, which efficiently (Faradaic efficiencies ranged from 88% to 100%) formed methanol when illuminated at 365 nm.^{[4](#page-8-0)} At −0.5 V vs SCE, the highest quantum yield for the 6-electron reduction to form methanol was 44%, yielding a 10.9% optical energy conversion efficiency.⁴ Other electrode systems and their Faradaic efficiencies for the conversion of carbon dioxide to methanol are shown in Table 3. Similar to the p-GaP electrode, experiments were conducted using a p -FeS₂ electrode to reduce $CO₂$. However, unlike p-GaP and Pd electrodes, the p -FeS₂ electrode was only capable of reducing $CO₂$ to formic acid and carbon monoxide. Both pyridine and imidazole were found to be effective electrocatalysts in this system.¹⁹ Our work also indicated that other aromatic amines were able to enhance the reduction of $CO₂$, including 1-ethyl-3-methyl imidazolium, which was proposed to operate through an N-heterocyclic carbene ylide-like intermediate.

Table 3. Comparison of Electrode Potentials and Efficiencies for the Conversion of Carbon Dioxide to Methanol

electrode	E (V vs SHE)	Faradaic efficiency (%)	ref
p-GaP	-1.16	60	21

RuO ₂ /TiO ₂	-0.56	60	28

In addition to the experimental work of our group[,3,4](#page-8-0)[,20,29](#page-9-0)[−][33](#page-9-0) the 6-electron reduction of $CO₂$ to methanol in the presence of pyridinium at a Pd electrode has been computationally explored by Batista, $33,34$ Musgraves, $35-38$ $35-38$ $35-38$ and Keith and Carter.^{[39](#page-9-0)–[42](#page-9-0)} The mechanism of $CO₂$ photoelectrochemical reduction using p-GaP/pyridinium has also been extensively investigated by some of the same parties: Bocarsly, Carter,^{[43](#page-9-0)–[45](#page-9-0)} and Musgraves.^{[37](#page-9-0)} While there are still disagreements about a suitable mechanism most notably voiced by Savéant, 46 there is general agreement that the mechanism is surface confined, involving inner sphere and hydrogen atom transfer processes. The various mechanistic possibilities in this system have been previously reviewed by Lakkaraju, Bocarsly and co-workers.⁴

4. HOMOGENEOUS CARBON DIOXIDE REDUCTION INVOLVING MANGANESE COMPLEXES

Lehn et al. were the first to report that $fac\text{-}ReLU(\text{bpy})(CO)_{3}$ was a photo- and electrocatalyst for the reduction of $CO₂$ to CO.^{[48](#page-10-0)} While this complex is able to act as both a homogeneous catalyst and photosensitizer, Lehn and coworkers found that photodecomposition occurs under near-UV irradiation, which is needed to perform the reaction. 49

It was not until 2011 that the first analogous manganese polypyridyl electrocatalyst, MnBr(bpy)(CO)₃, was reported by Deronzier et al.[50](#page-10-0) This was nearly 50 years after the synthesis of fac -MnI(bpy)(CO)₃ was reported in 1959 by Abel and Wilkinson.^{[51](#page-10-0)} One of the greatest challenges associated with utilizing Mn polypyridyl complexes is their extreme photosensitivity in solution, which leads to decomposition upon exposure to room light via loss of CO ligands. This prevents them from acting as photochemical reagents and poses an additional challenge in studying them electrochemically.

In order to explore this chemistry further, a complex was needed that did not undergo rapid photochemical degradation under room light. However, given that $MnBr(bpy)(CO)$ ₃ was already a known electrocatalyst, our research group was initially interested in the electrocatalytic mechanism and catalytic efficiency. In an effort to circumvent this problem, we presented the synthesis and characterization of the first catalytic manganese N-heterocyclic carbene complexes for the electrocatalytic reduction of $CO₂$ to CO in 2014.^{[52](#page-10-0)} Based on the manganese(I) complexes following the form fac -MnBr(N− $N(CO)_3$, where N–N is a bpy ligand, a single pyridine ring in bpy was replaced with one N-heterocyclic carbene (NHC) moiety to change the metal coordination environment. The

advantage of such an approach allows for the incorporation of NHC ligands that are 4-, 5-, or 6-membered.

Under an atmosphere of $CO₂$, both manganese NHCpyridine species showed a current enhancement that fell only slightly below that of the parent complex, $MnBr(bpy)(CO)_3$ when in wet $(5\% \text{ v/v H}_2\text{O})$ MeCN with 0.1 M tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte. We also reported that the first- and second-electron reductions occurred at approximately the same potential for both NHC-pyridine containing complexes when compared to the parent compound, which showed a difference between the two sequential one-electron reductions of several hundred millivolts. Consistent with an electron transfer−chemical reaction−electron transfer (ECE) mechanism, the first reduction wave of the NHC-pyridine complex corresponded to the formation of a doubly reduced anionic species, followed by the loss of the bromide anion. This allows for the coordination and subsequent two-electron reduction of $CO₂$ to CO. The second, smaller reduction peak was reported to correspond to the reduction of a small quantity of a Mn−Mn dimer species, $[\{Mn(NHC-pyridine)(CO)\}^3_2]$.

As previously stated, one of the major problems with working with these Mn complexes was their rapid photochemical degradation under room light. To see whether the photostability of these complexes could be improved, we replaced the Br[−] axial ligand of MnBr(N−N)(CO)₃ with either CN[−] or NCS[−] to explore the effect of the axial ligand on photodecomposition.[53](#page-10-0) By substituting CN[−] for Br[−], we were able to improve the photostability of the complex significantly (5×) under 420 nm illumination due to resulting blue-shifted MLCT band. For $MnBr(Et-Im-Py)(CO)$ ₃ and $MnNCS(Et-Im-Py)$ $Py)(CO)_{3}$, the initial yellow complexes in DMSO quickly turned red-brown when exposed to room light, whereas the two complexes with CN ligands in the axial position, $MnCN(Et-Im-Py)(CO)$ ₃ and $MnCN(Et-BIm-Py)(CO)$ ₃ remained their initial yellow color even after many days of exposure to room light. This was attributed to the strong-field nature of the cyanide ligand relative to thiocyanate and bromide.

While the manganese polypyridyl complexes have similarities to their rhenium counterparts, one notable difference is that manganese complexes require the addition of weak Brønsted acids in order to reduce $CO₂$ to $CO₂$ ^{[53](#page-10-0),[54](#page-10-0)} The effect of a Brønsted acid upon the system is thought to be 2-fold: (1) the acid will stabilize the O atom of $CO₂$ through hydrogen bonding and (2) it will facilitate C−O bond cleavage of $CO₂$ needed to produce $CO⁵⁵$ As shown in Figure 4, to compare the effects of intermolecular and intramolecular H-bonding, we were able to incorporate an intramolecular H-bond in the second coordination sphere by adding a phenol in the 6-

Figure 4. Schematics of the manganese complexes comparing intramolecular hydrogen bonding (left) vs adding a Brønsted acid (right). Adapted with permission from ref [56](#page-10-0). Copyright 2015 American Chemical Society.

position of the bipyridine ring. 56 The resulting ligand, 6-(2hydroxyphenyl)-2,2′-bipyridine (HOPh-bpy), would then be able to coordinate to the O of $CO₂$.

Under an atmosphere of $CO₂$, MnBr(HOPh-bpy)(CO)₃ was reported to display an 11-fold current enhancement from 0.58 mA/cm² to 6.3 mA/cm² at the potential of the second reduction wave. This current enhancement was 7 times greater than the current enhancement seen for $MnBr(bpy)(CO)$ ₃ at approximately the same overpotential. To investigate whether the improved $CO₂$ reduction was due to the presence of a phenolic proton in the second coordination sphere, the 6 position of bpy was replaced with anisole to form MnBr- $(MeOPh\text{-bpy})(CO)$ ₃. This complex only displayed a 2.1× current enhancement under $CO₂$ atmosphere, indicating that the current increase was in fact due to the phenolic proton. When only 1 mM MnBr(bpy)(CO)₃ was evaluated with wet (5% v/v water) MeCN with and without 10 mM phenol, the catalytic rate was observed to decrease with the addition of phenol. This confirmed that the addition of phenol alone could not be responsible for the current enhancement observed for $MnBr(HOPh\text{-bpy})(CO)$ ₃. Using theory, we suggested that the source of this increased activity came from a lower entropic barrier to an intramolecular mechanism for proton-assisted dehydration of the Mn(6-(2-hydroxyphenyl)-bpy)- (CO) ₃COOH intermediate.^{[1](#page-8-0)}

Later, in 2019, we presented a mechanistic study that explored the viability of the proposed pendent H-bond donors.[57](#page-10-0) While the previous study attached H-bond donors in the 6-position of the bipyridine ring, this study synthesized $MnBr(HOPh-bpy)(CO)_3$ analogues, in which HOPh was placed in the 4- and 5-positions as well. This was in addition to comparing the electrocatalytic activity of the same complexes using MeOPh instead, which does not have H-bonding ability. We observed that significant current enhancement for $CO₂$ reduction was only seen when the H-bond donor was in the 6 position on the bipyridine ring, as this would be the closest position to the ligated Mn center. The X-ray structures also showed that the 4- and 5-substituted complexes had increased torsion angles between the phenol and bipyridine ring relative to the 6-substitued complex as a result of increased steric interference between the phenol and Mn center.

More recently, we synthesized a variety of fac-MnBr(N− $N(CO)$ ₃ complexes, shown in [Figure 5](#page-6-0), where the N−N ligand was 1,10-phenanthroline, bipyrizine, or bipyridine.^{[58](#page-10-0)} This was done in order to understand the effects on the bipyridine π^* energy level and the electrocatalytic conversion of CO2 to CO. UV−vis, cyclic voltammetry, and density functional theory calculations were employed showing that adding electron-withdrawing substituents to the 4,4′-position of the bipyridine ligand red-shifted the MLCT band, leading to poorer $CO₂$ conversion to CO. The LUMO energy levels, which correlated to the bpy π^* energy level, were calculated to be more negative as electron withdrawing groups were incorporated on the bpy. This led to smaller MLCT energy and a positive shifted first peak potential. The resulting decrease in $CO₂$ conversion was attributed to slower axial Br[−] loss, as the internal conversion from the bpy π^* orbital to the metal d−σ* scaffold of orbitals became more difficult with a smaller MLCT energy gap. Second, the HOMO of the doubly reduced species was less electron dense with electron-deficient complexes, making it more difficult to bind to $CO₂$.

One of the proposed intermediates of the monomeric $MnBr(bpy)(CO)$ ₃ electrocatalytic cycle is believed to be the

Figure 5. Scope of manganese complexes synthesized. Adapted with permission from ref [58](#page-10-0). Copyright 2019 American Chemical Society.

tricarbonyl complex, $[Mn(bpy)(CO)_3]^-$. During this cycle, shown in [Figure 6](#page-7-0), the cationic tetracarbonyl complex is thought to form in solution after reaction with $CO₂$ and two protons. We successfully synthesized the tetracarbonyl intermediate and characterized it via IR and UV−vis spectroscopy.^{[59](#page-10-0)} It was found through in situ UV-vis under Ar, that at the second reduction potential $(-1.88 \text{ V} \text{ vs } \text{Fc}/\text{Fc}^+)$ both $[Mn(bpy)(CO)_3]$ ⁻ and the Mn−Mn bonded dimer formed. It was also reported using IR spectroscopy before and after electrolysis at the first reduction potential (−1.48 V vs Fc/Fc^+) that both $\text{[Mn(bpy)}(\text{CO})_3]^-$ and the Mn−Mn bonded dimer formed. Radiolabeled $^{13}CO_2$ was employed, and via gaseous IR spectroscopy it was shown that ${}^{13}CO_2$ could be electrocatalytically converted to ${}^{13}CO$. Though the axial ligand in the Mn parent complex, which has been identified to dissociate first, is typically a halide, such as Br[−], we found through IR analysis that axial CO dissociation will occur after the complex has been singly reduced. In essence, the axial ligand need not necessarily be a halide for $CO₂$ electroreduction to occur.

As a result of the extreme photosensitivity of Mn complexes, various groups such as ours have attempted to modify the $[MnX(N-N)(CO)₃]$ scaffold (where N–N is a polypyridyl ligand) in an effort to improve its photostability.^{[60](#page-10-0)–[65](#page-10-0)} Building upon our group's previous work of shifting the MLCT band

into the UV-region by substituting the axial Br[−] ligand with a CN[−] ligand, a novel CN-bridged dimer was synthesized to enhance the photostability of these Mn complexes.^{[2](#page-8-0)}

By substituting the Br[−] axial ligand of the monomer species with the strong π -acceptor, CN⁻, the MLCT band was shifted from 417 to 375 nm, which led to the development of a novel, cationic cyanide-bridged dimanganese species, {[Mn(bpy)- $(CO)_3]_2(\mu$ -CN)}ClO₄. This species, abbreviated Mn₂CN⁺, is represented in [Figure 7](#page-7-0) and features a MLCT at 364 nm. We demonstrated that Mn_2CN^+ was both electrocatalytically and photochemically active for $CO₂$ reduction to CO without the introduction of an added photosensitizer.

In a 4 h bulk electrolysis with the potential held near the second reduction peak at -1.90 V vs Fc/Fc⁺, MnBr(HOPhbpy)(CO)₃, Mn₂CN⁺, displayed a maximum ξ of 90%, compared to the ξ of the parent complex MnBr(bpy)(CO)₃Br, which was at 75%. While the use of $MnBr(bpy)(CO)_{3}$ and $MnCN(bpy)(CO)$ ₃ to photochemically reduce CO_2 to CO is implausible without an added photosensitizer given their rapid photodegradation, the Mn_2CN^+ complex was able to photochemically reduce $CO₂$ with either 5% v/v water or 1 M phenol as the proton source in CO_2 -saturated MeCN. Using radiolabeled ${}^{13}CO_2$, we were able to show via FT-IR spectroscopy that the CO produced arose from $CO₂$ reduction.

Figure 6. Electrocatalytic cycle for MnBr(bpy)(CO)₃ reducing CO₂ to CO. Adapted with permission from ref [58](#page-10-0). Copyright 2019 American Chemical Society.

Figure 7. Representations of the cyanide bridged dimanganese species and its two monomeric precursors. Reproduced with permission from ref [2.](#page-8-0) Copyright 2019 The Royal Society of Chemistry.

The photophysical properties of Mn_2CN^+ were studied via UV−vis and IR under irradiation at 365 nm. The UV−vis displayed a shoulder that rose around 520 nm and a clear isosbestic point at 420 nm after irradiation, indicating a one-toone conversion of Mn_2CN^+ into a photoproduct. IR studies revealed that upon irradiation, the carbonyl peak trans to the C of the bridging cyanide ligand selectively disappeared. It was thought that the photoproduct was a solvato species, where the coordinating MeCN solvent replaced the CO_{axial} on the C-end of the complex. We also showed that using 2-MeTHF, a weakly coordinating solvent, did not result in the formation of an isosbestic point in the UV−vis.

Additional FT-IR studies with continuous photolysis revealed that peaks evolved at 1870 and 2120 $\text{cm}^{-1},$ corresponding to a carbonyl stretching mode and a shifted bridged-CN mode postirradiation.^{[66](#page-10-0)} DFT calculations indicated that these features were unique to the solvated species, s- Mn_2CN^+ , in which the axial position trans to the C-end of the bridging cyanide ligand was coordinated by MeCN, rather than on the N-end of the molecule. Transient absorption spectroscopy was also employed, showing that the excited state lifetime of Mn_2CN^+ was 7 ns and was stabilized by coordinating MeCN solvent.

5. FUTURE DIRECTIONS

A variety of scientific challenges remain in the understanding of $CO₂$ chemistry at a level that could lead to practical systems for the efficient utilization of this compound as a fossil fuel substitute. All of the fuel and feedstock transformations of interest to our group are thermodynamically uphill processes. Thus, energy requirements must be meticulously considered, with the differences between activational free energies and free energies of reaction carefully segregated and regulated. Control over the hydrogen-bonding environment, interfacial proton gradients, and coupling of multielectron and electron−proton processes all provide access to the lowest energy reaction channels.

The largest and perhaps most important challenge in carbon dioxide electrochemistry is understanding and controlling carbon−carbon bond formation. To date, very few systems are known that are able to carry out the transformation of $CO₂$ to C2+ products. It is a mastery of these reactions that will allow $CO₂$ to truly become an alternate chemical platform to fossil-based resources.

Currently, we only have a partial understanding of the multiple charge carrier processes and even less of an understanding of how to control such processes. Thus, the rational design of both molecular and electrode interfacial electrocatalysts remains out of immediate reach. Yet, our understanding of such interactions is close to the point of application. Therefore, it is reasonable to believe that in the near future, the regulated activation of carbon dioxide will be a matter of applying rules that regulate multi-PCET processes. At the current time, we are mainly observers of chance systems that generate hydrocarbons from $CO₂$. A detailed mechanistic understanding of these reactions is essential to the further development, control, and application of $CO₂$ as a feedstock chemical, while providing a non-fossil-fuel-based entry point to the organic chemistry on which our society depends.

Biographies

Kailyn Y. Cohen graduated from Ursinus College in 2020 with a B.S. in Chemistry and earned her M.A. degree from Princeton University in 2022. Her undergraduate research focused on the electrochemistry of bimetallic proteins as well as carbon dioxide photoreduction. As a graduate student in the Bocarsly lab at Princeton University, Kailyn currently studies the photo- and electrochemical aspects of $CO₂$ reduction using manganese complexes.

Rebecca Evans graduated from Rhodes College in 2019 with a B.S. in Chemistry with a minor in Physics and earned her M.A. degree from Princeton University in 2021. She conducted undergraduate research

in the field of computational drug design with Dr. Mauricio Cafiero. Rebecca is currently a graduate student in the Bocarsly lab at Princeton University performing density functional theory calculations on various electrochemically active species. Her interests lie in environmental chemistry and theoretical chemical calculations.

Stephanie Dulovic received her B.S. in Biochemistry from Adelphi University in 2020 and her M.A. degree from Princeton University in 2022. Her undergraduate research with Dr. Justyna Widera-Kalinowska was on the topic of photoelectrochemistry, with a focus on inorganic semiconductors and conducting polymers. Stephanie is now a graduate student in the Bocarsly Lab at Princeton University investigating carbon nitride materials and metal alloys as photoelectrocatalysts and electrocatalysts for carbon dioxide reduction.

Andrew B. Bocarsly is a Professor in the Department of Chemistry at Princeton University. He earned his Ph.D. in Chemistry at MIT in 1980 and his B.S. in Chemistry and Physics from UCLA in 1976. His interests lie in transformations of $CO₂$, photochemistry, semiconductor photoelectrochemistry, and electrocatalysis. He sits on the International Scientific Advisory Board for the International Conference on Carbon Dioxide Utilization (ICCDU) and is an Editorial Advisory Board Member for The Journal of $CO₂$ Utilization. He cofounded Liquid Light, Inc. in 2009.
